

# VARIATIONS OF DNA

*Ho Huynh Thuy Duong*

*University of Science*

## What is the meaning of DNA variations in living world ?

### Negative effects

- ⌘ At the scale of the living world, high DNA variations would prevent the maintenance of species
- ⌘ For a living organism, they usually have lethal effects

### Positive effects

- ⌘ Without these variations, the Evolution of Life on Earth would not be possible, new species could not be created and the existing biodiversity would not be observed

**Thus, challenging problem for the living world is how to maintain a relative stability of genetic material while allowing variations at a certain level.**

**This is actually realized by repair systems which, however, do not perfectly reverse all variations on DNA**

# **VARIATIONS OF DNA INCLUDE :**

**∞ DNA MUTATIONS**

**∞ DNA RECOMBINATION – HOMOLOGOUS AND  
SITE-SPECIFIC RECOMBINATION**

**∞ DNA TRANSPOSITION**

# **DNA MUTATIONS**

## WHAT KIND OF MUTATIONS DOES DNA UNDERGO DURING ITS EXISTENCE?

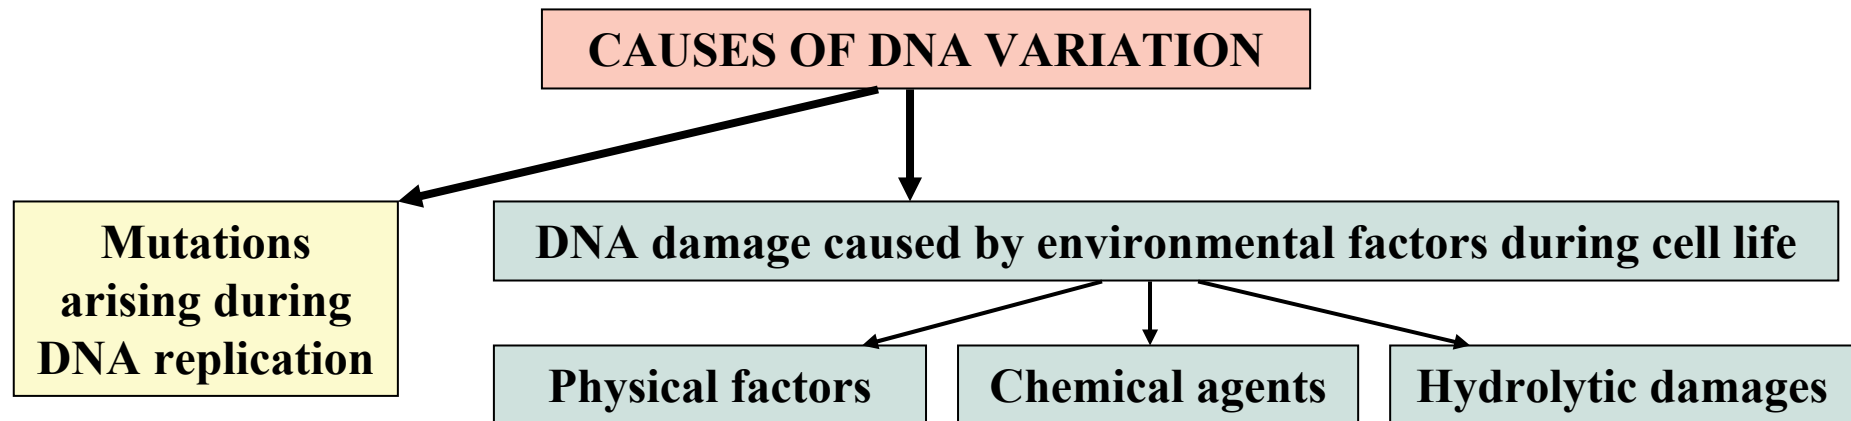

1. **Point mutations** : insertion or deletion of one base and base substitutions including :

☞ Transitions : pyrimidine → pyrimidine, e.g T→C ; purine → purine, e.g A→G

☞ Transversions : pyrimidine → purine, e.g T →G/A ; purine → pyrimidine, e.g A→C/T

2. **Insertions, deletions** of large DNA fragments and **rearrangements** of the chromosomes

### What are the causes of DNA mutations ?

### What are the consequences of DNA variations ?

1. Blocking DNA replication and transcription → cell death

2. Altering bases → mispairing → mutations → cell mutated

## **HOW DOES CELL MAINTAIN ITS DNA INTEGRITY ?**

**MAINTENANCE OF DNA INTEGRITY IS ASSURED BY REPAIR SYSTEMS WHICH OPERATE DURING DNA REPLICATION OR BETWEEN TWO REPLICATION ROUNDS**

# REPAIR OF REPLICATION ERRORS

**During replication**, misincorporation of nucleotides can occur.

These errors can be repaired in two ways :

∞ Many DNA polymerases have **proofreading function** which uses 3'-5' exonuclease activity to eliminate the wrongly incorporated nucleotide during replication process.

∞ Some of the misincorporated nucleotides which escape proofreading could be recognized and eliminated just after finishing replication by the **mismatch repair system**.

The **mismatch repair system** has two functions :

1. Rapidly detects the mismatches before they being fixed at the next round of replication
2. Accurately corrects the mismatches, that is always replacing the mismatched nucleotide in the daughter strand, never in the parental strand

*DNA polymerase proofreading : a misincorporated nucleotide blocks the replication ; DNA polymerase 3'-5' exonuclease activity hydrolyzes the unmatched nucleotide and allows synthesis process to continue.*

# MISMATCH REPAIR SYSTEM

In *E. coli*, the mismatch repair system is composed of many components - MutS, MutL, MutH : (1) **MutS** detects the mismatch through distortion it causes to the DNA structure and binds to the region containing the mismatch, (2) **MutL** activates **MutH**, (3) **activated MutH** causes a nick on one strand near the region containing the mismatch, (4) **A helicase, UvrD**, unwinds the DNA toward the site of the mismatch, (5) **An exonuclease** digests the displaced single strand including the site of the mismatch, (6) **DNA polymerase III** fills in the single-stranded gap, (7) **A ligase** seals the nick.

**How does the mismatch repair system work accurately through distinguishing the parental from the daughter strand ?**

All the A residues belonging to the sequence 5' GATC 3' throughout *E. coli* genome are methylated. Just after the replication fork passes, each daughter strand is **hemi-methylated**, that is they are only methylated on the initial parental strand. Thus, before **Dam methylase** methylates the newly synthesized strand, there is a moment when the repair system can recognize the newly synthesized strand and corrects the mismatch on it.

Eukaryotes have a homolog system to the *E. coli* mismatch repair system composed of **MSH (MutS homologs)** and **MLH (MutL homologs)/PMS**. But they lack MutH and the capacity of recognizing the newly synthesized strand based on hemi-methylation.

The repair process is based on the lagging strand sequence composed of many Okazaki fragments separated by nicks which are considered as nicks created by MutH on the newly synthesized strand in *E. coli*.

# DNA DAMAGES CAUSED BY ENVIRONMENTAL FACTORS

## HYDROLYTIC DAMAGES

Water can cause DNA damages through : (1) **deamination** transforming C to U, 5-methyl C to T and (2) **depurination** which gives rise to abasic sites in the DNA (*figure*).

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

## CHEMICAL DAMAGES

☞ Mutagens such as alkylating agents, nitrous acid can alter DNA structure through ethyl/methylation or deamination.

☞ Base analogs are derivatives of normal bases with altered base pairing properties, e.g the enol tautomer of 5-bromouracil base pairs with G instead of A.

☞ Intercalating agents (ethidium, acridine) which bind to purine and pyrimidine bases of DNA generate insertions and deletions.

## PHYSICAL DAMAGES

☞ Ionizing radiations (X-rays,  $\gamma$ -rays) generate free radicals. The free radicals transform G to oxoG which can base pairs with either C and A. Ionizing radiations can also cause double strand breaks.

☞ Non-ionizing radiation such as ultra violet light supply energy to create new chemical bonds. The most important form of DNA damage is the formation of pyrimidine dimers.

# REPAIR SYSTEMS FOR DNA DAMAGES

Four categories of repair systems are involved in DNA damage repair : Direct reversal repair, Excision repair, Recombinational repair, Translesion synthesis

## DIRECT REVERSAL REPAIR SYSTEMS

Repair enzymes directly reverse the damage. In **photoreactivation**, the enzyme DNA photolyase uses energy from visible light to break bonds forming pyrimidine dimers (*figure*). The enzyme **methyltransferase** reverses the damage caused by alkylation by removing and retaining the methyl group from altered bases.

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.248, fig 9.11. Benjamin Cummings., CSHL Press”*

# EXCISION REPAIR SYSTEMS - BASE EXCISION REPAIR

Excision repair systems include the Base excision repair and the Nucleotide excision repair

## 1. Base excision repair :

A **DNA glycosylase** removes the wrong base. The remaining nucleoside is then removed by an endonuclease. The gap is filled in by a repair DNA polymerase using the intact strand as template and is finally sealed by DNA ligase

*(A) Base excision repair. An uracil DNA glycosylase removes a deaminated C. After that, the remaining sugar phosphate is cut out by the action of AP endonuclease and a phosphodiesterase. The gap of a single nucleotide is then filled by DNA polymerase and DNA ligase.*

“Copyright 2002 from *Molecular Biology of the Cell* by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”

April 2009

# EXCISION REPAIR SYSTEMS - NUCLEOTIDE EXCISION REPAIR

*Functions of NER repair proteins:*

**Detect the distortion of DNA due to mutation.**

**Separate the two strands and recruit UvrC**

**Cut the single strand bearing the mutation at two sites : at 8 nucleotides upstream and four nucleotides downstream of the site of mutation.**

**Helicase, releases the cut segment**

**Finally, DNA polymerases fills in the gap and DNA ligase seals the nick.**

*E. Coli – 4 proteins*

**UvrA**

**UvrB**

**UvrC**

**UvrD**

*Eukaryote – more than 25 proteins*

**XPC**

**XPA, XPD**

**ERCC1-XPF, XPG**

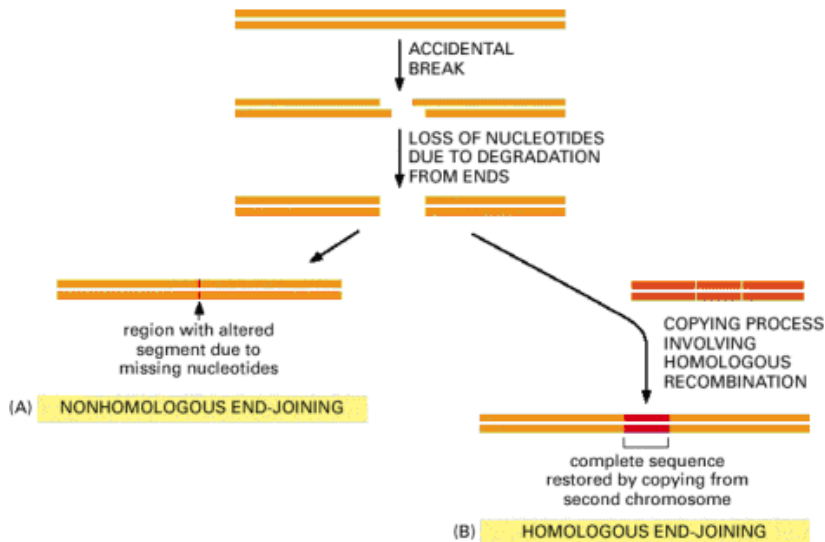

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

*(B) Nucleotide excision repair. Distortion of DNA backbone due to thymine dimer is recognized, cuts are made on each side of the lesion, and a DNA helicase removes the cut segment*

# RECOMBINATION REPAIR SYSTEMS

## RECOMBINATIONAL REPAIR SYSTEMS INCLUDE DOUBLE STRAND BREAK (DSB) REPAIR & NON HOMOLOGOUS END JOINING (NHEJ)

These two repair systems are activated when the double helix is broken and no single strand can be used as template to correct the other strand.

**DSB REPAIR**  
 Sister chromosome is used as template to synthesize the broken double-stranded DNA through homologous recombination

**NHEJ REPAIR**  
 If DSB arises before sister chromosome is made, the broken DNA could be religated or is repaired by NHEJ systems as follows :

“Copyright 2002 from *Molecular Biology of the Cell* by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”

# TRANSLESION DNA SYNTHESIS

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.255, fig 9.18. Benjamin Cummings., CSHL Press”*

When DNA synthesis is blocked by a non repaired mutation, a **translesion DNA polymerase** will replace the replicative DNA polymerase.

The translesion DNA polymerases in *E. coli* are **UmuC and UmuD'**. They can incorporate nucleotides independently of base-pairing propriety.

Activities of translesion DNA polymerases : (1) allow cell survival by bypassing the lesion which blocks DNA replication, (2) induce important mutagenesis

This phenomenon is called **“SOS response”** and is only used as the last resort.

# SOME HUMAN DISEASES CAUSED BY DEFECTS IN DNA REPAIR SYSTEMS

**Table 5-2. Inherited Syndromes with Defects in DNA Repair**

NAME	PHENOTYPE	ENZYME OR PROCESS AFFECTED
MSH2, 3, 6, MLH1, PMS2	colon cancer	mismatch repair
Xeroderma pigmentosum (XP) groups A–G	skin cancer, cellular UV sensitivity, neurological abnormalities	nucleotide excision-repair
XP variant	cellular UV sensitivity	translesion synthesis by DNA polymerase $\delta$
Ataxia–telangiectasia (AT)	leukemia, lymphoma, cellular $\gamma$ -ray sensitivity, genome instability	ATM protein, a protein kinase activated by double-strand breaks
BRCA-2	breast and ovarian cancer	repair by homologous recombination
Werner syndrome	premature aging, cancer at several sites, genome instability	accessory 3'-exonuclease and DNA helicase
Bloom syndrome	cancer at several sites, stunted growth, genome instability	accessory DNA helicase for replication
Fanconi anemia groups A–G	congenital abnormalities, leukemia, genome instability	DNA interstrand cross-link repair
46 BR patient	hypersensitivity to DNA-damaging agents, genome instability	DNA ligase I

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

# **DNA RECOMBINATION**

# HOMOLOGOUS RECOMBINATION

*All DNA is recombinant DNA (\*)*

∞ **Homologous recombination (general recombination):** Exchange of homologous regions between two DNA molecules.

∞ The main biological roles of homologous recombination :

(1) **Inducing genetic variability through formation of recombinant DNA.** During meiosis in eukaryotes, homologous recombination is needed for correct pairing of chromosomes ; it creates new combinations of genes which are transmitted to the descendants

(2) **Controlling DSB repair system**

(3) **Regulating gene expression by transferring genes between “dormant” or “active” sites in the genome, e.g genes controlling mating types in yeast (MAT locus)**

∞ **Homologous recombination is the basis of many methods used to create “transgenic” or “knock-out” organisms.**

∞ **Homologous recombination can be explained by [Holliday model](#)**

(\*) <sup>April 2009</sup> *Watson, J.D., Baker, T.A., Bell, S.P., Gann, A., Levine, M., Losick, R. Molecular Biology of the Gene, 5<sup>th</sup> ed, Cold Spring Harbor Laboratory Press. San Francisco.*

# HOLLIDAY MODEL

(a) **Alignment** of two homologous DNA

(b) **Creation of break** in a single strand of each DNA molecule

(c) Base pairing between a single-stranded region of one DNA molecule with its complementary strand on the homologous DNA molecule. This step is called **strand invasion** and results in a structure called **Holliday junction**

(d) The Holliday junction moves along the DNA. This step is called **branch migration**. This process increases the length of exchanged DNA regions.

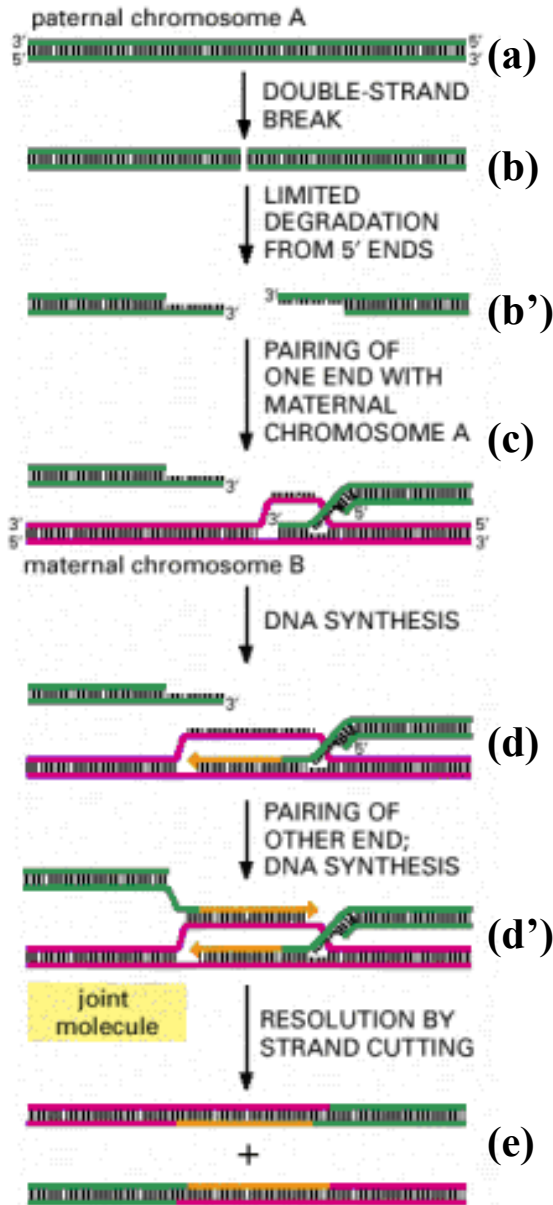

(e) Cleavage of the Holliday junctions. This step is called **resolution**.

Resolution of Holliday junction could be done in two ways : the cuts marked (1) result in **crossover products** whereas the cuts marked (2) give rise to **non crossover products** containing a fragment of “**hybrid DNA**”

April 2009  
Crossover products

Non crossover products

# HOMOLOGOUS RECOMBINATION PROCESS THROUGH DSB

In reality, homologous recombination is often initiated by **DSB**. Meiotic crossing over is a result of this process including many steps :

(a) Alignment of two homologous DNA, e.g two alleles of a gene.

(b) Creation of double strand break in one DNA molecule

(b') Formation of single-stranded ends of broken DNA by nuclease activities.

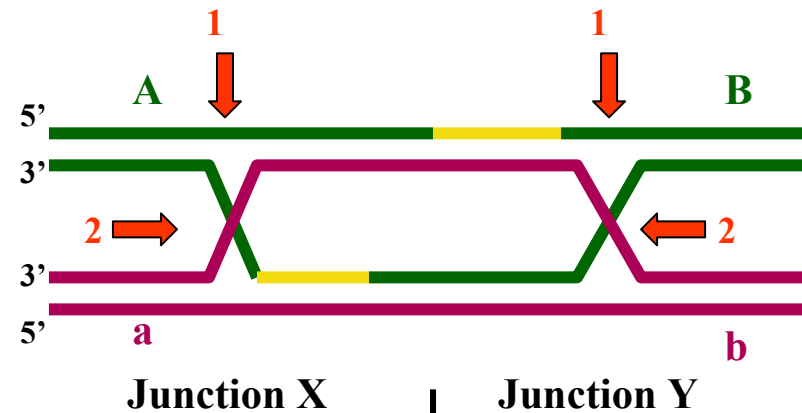

(c) Strand invasion : Base pairing between a single-stranded region of one DNA molecule with its complementary strand on the homologous DNA molecule to form the Holliday junction

(d) Branch migration : The Holliday junction moves along the DNA. The invading strands (*in green*) serve as primers to synthesize new DNA fragment (*in yellow*) to replace the region cleaved at (b')

(d') Second Holliday junction is formed and subsequent branch migration

(e) Resolution of the Holliday junctions.

# RESOLUTION OF HOLLIDAY JUNCTIONS CREATED BY DSB

“Adapted from Watson J.D. et al. 2004. *Molecular Biology of the Gene*. 5<sup>th</sup> edition, p.266, box 10.1, fig 1. Benjamin Cummings., CSHL Press”

There are many ways to resolve Holliday junctions created by DSB. A rule determines whether cross over or non cross over products are made.

- ☞ If the two junctions are resolved in the same way (both at site 1 or 2), non cross over products will be made
- ☞ If the two junctions are resolved in different ways (one at site 1, the other at site 2 and *vice versa*), cross over products will be made

# HOMOLOGOUS RECOMBINATION MACHINERY IN *E. COLI*

Proteins involved in homologous recombination in *E. coli* are listed by order of their participation in the process as follows :

RECOMBINATION STEP	RECOMBINATION FACTORS
Creation of DSB on one DNA molecule	No specific protein. DSB in prokaryotes usually results from DNA damage
Generating single-stranded 3' end from DSB	RecBCD complex
Strand invasion : base pairing and strand exchange between homologous DNA, resulting in the Holliday junction	RecA
Branch migration	RuvAB
Resolution of the Holliday junction	RuvC

# PROKARYOTIC HOMOLOGOUS RECOMBINATION FACTORS

**RecBCD complex** is composed of three proteins RecB, C, D and has two enzymatic activities, helicase and nuclease. This complex operates as follows :

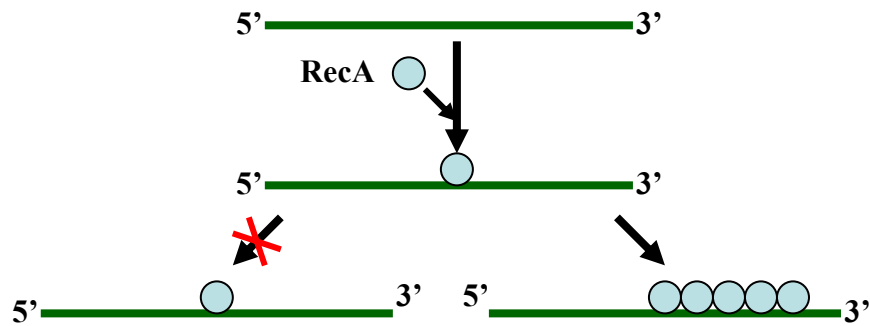

☞ RecBCD complex binds to a site of DNA double strand break, moves along the DNA, progressively unwinds and cleaves the two strands.

☞ When it encounters a **chi ( $\chi$ ) site (5'-GCTGGTGG-3')**, its nuclease activity changes so that it preferentially cleaves the strand having the **5'-3' polarity**, resulting in a **3' overhang single strand**

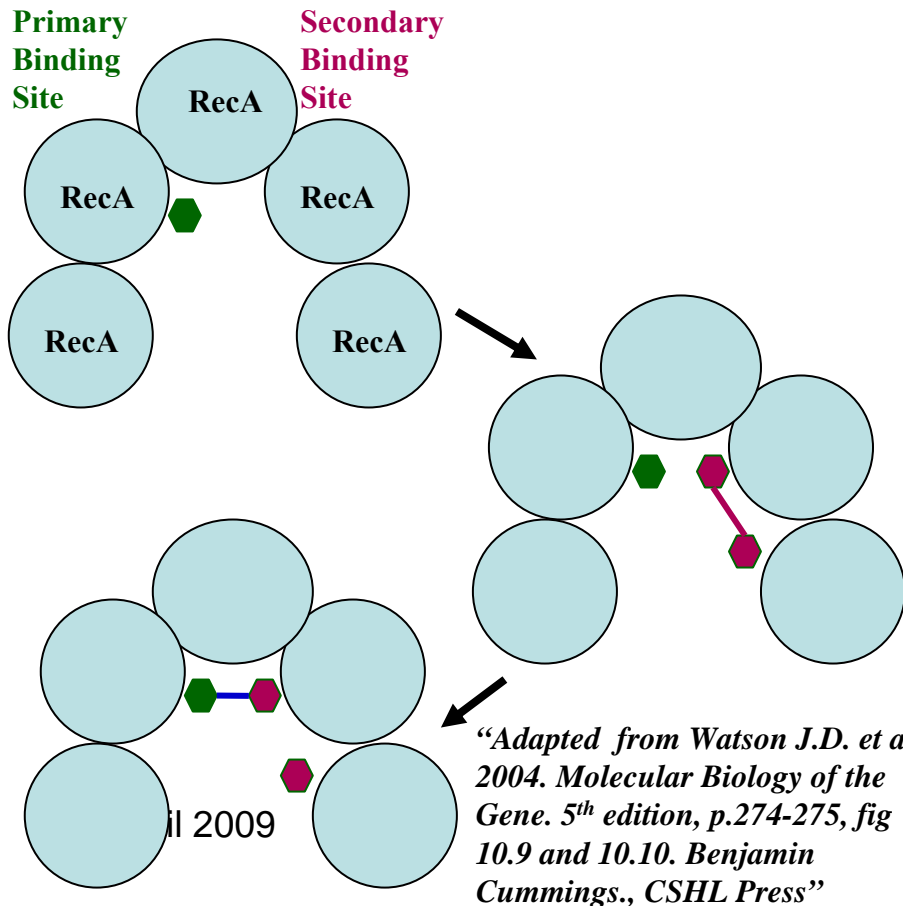

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.270, fig 10.5. Benjamin Cummings., CSHL Press”*

**The 3' single-stranded region is required for the binding of strand-exchange protein RecA to promote recombination**

# PROKARYOTIC HOMOLOGOUS RECOMBINATION FACTORS

Many **RecA** subunits (~100) assemble on the 3' single-stranded DNA to form a protein-DNA filament. This assembly grows in the 5'→3' direction → only 3' overhang DNA strand could be the substrate for RecA binding.

Functions of RecA : (1) Search for sequences complementarity, (2) base pairing between homologous DNA and strand exchange

∞ To search for sequence matches, RecA keeps the **single strand** in its primary binding site and screens many **DNA molecules** through their transient binding to the secondary binding site.

∞ When the region of complementarity is found, RecA mediates **strand exchange** through breaking old set of base pairs (—) and formation of new one (—) → switch of base pairing between the three DNA strands

# PROKARYOTIC HOMOLOGOUS RECOMBINATION FACTORS

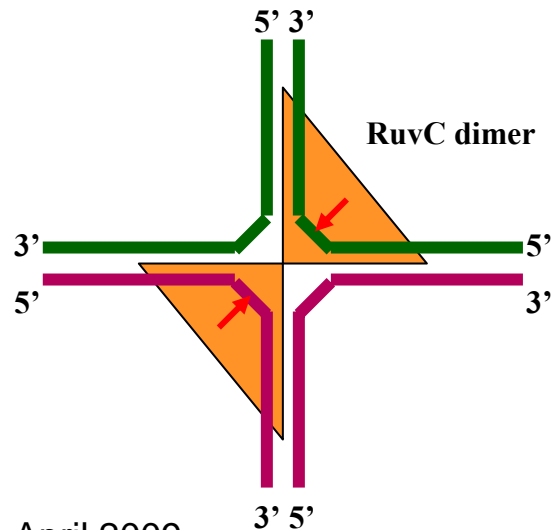

**RuvAB** complex mediates **branch migration** :

∞ **RuvA tetramer** recognizes and binds to Holliday junction, recruits two RuvB hexamers

∞ **RuvB hexamer** is an ATPase which provides energy to drive strand exchange leading to branch migration

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.277, fig 10.12. Benjamin Cummings., CSHL Press”*

**RuvC** resolves the **Holliday junction** by cleaving (↓) the two homologous strands belonging to the two DNA duplexes.

The cleaved ends are then joined by DNA ligase.

Depending on the strand pairs cut, resolution of Holliday junction can give rise to cross over or non cross over products.

April 2009

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.278, fig 10.13. Benjamin Cummings., CSHL Press”*

# RECOMBINATION FACTORS IN PROKARYOTES AND EUKARYOTES

Recombination process in prokaryotes (*E. coli*) and eukaryotes are very similar including specific recombination proteins having similar functions acting in the same order

<u>RECOMBINATION STEP</u>	<u><i>E. COLI</i></u>	<u>EUKARYOTE</u>
Generating DSB	None	Spo 11, HO
Generating single strands	RecBCD	MRX (Rad50/58/60)
Assembly of strand exchange proteins	RecBCD	Rad52, Rad59
Pairing homologous DNAs and strand invasion	RecA	Rad51, Dcm1
Holliday junction recognition and branch migration	RuvAB	Unknown
Resolution of Holliday junction	RuvC	Mus81, ... ?

# SITE-SPECIFIC RECOMBINATION

Site-specific recombination (SSR) does not involve long similar DNA sequences as in homologous recombination. It occurs between short DNA sequences known as recombination sites.

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.296, fig 11.4. Benjamin Cummings., CSHL Press”*

SSR occurs when the protein recombinase recognizes and binds to recombination sites on DNA. Recombination site includes two types of sequences : two recombinase recognition sequences bound by recombinase flanking a crossover sequence where DNA cleavage and rejoining occur.

SSR can make DNA rearrangements in three ways :

∞ Integration (insertion) : when crossover occurs between recombination sites of two different molecules

∞ Excision (deletion) : when recombination sites are direct repeats (→ →)

∞ Inversion : when recombination sites are inverted repeats (→ ←)

APRIL 2003  
*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

# SSR RECOMBINASES

**SSR recombinases** operate in two steps :

☞ When bound to recombination sites, recombinases induce single strand break and form a covalent bond with the cleavage site → formation of a protein-DNA intermediate.

☞ The cleaved DNA end on the other strand interacts with the protein-DNA intermediate, hydrolyzes the covalent bond. The released primary DNA end is then sealed with the second cleavage site using energy stocked in the protein-DNA intermediate → generation of recombinant molecules.

Recombinase + DNA end → Protein-DNA intermediate → DNA end + DNA end  
→ Recombinant molecule

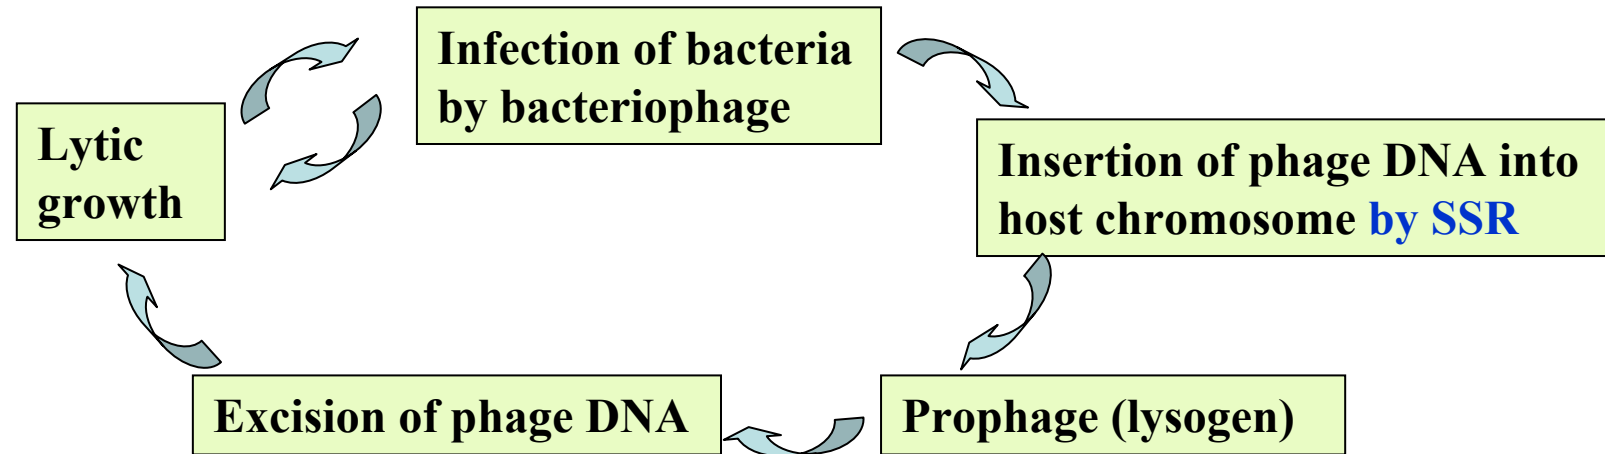

SSR recombinases are classified into two families : serine recombinases and tyrosine recombinases :

☞ **Serine recombinases** : The active group which interacts with DNA cleavage site is a **serine**. Four subunits of the enzyme work **simultaneously** to induce break in the four strands of the two exchanged DNA molecules → Strand swap → Reseal → Recombinant molecule.

☞ **Tyrosine recombinases** : The active group is a **tyrosine**. Two subunits of the enzyme cleave and rejoin two DNA strands first followed by the action of the other subunits.

# BIOLOGICAL MEANINGS OF SITE-SPECIFIC RECOMBINATION

Phage insertion into host chromosome is an example of site-specific recombination

**Modification of gene expression** through site-specific recombination, e.g. Hin recombination in *Salmonella*.

⌘ Flagellin is a surface protein of the bacteria, thus is a target of host immune system.

⌘ Genes encoding flagellin exist in two alternative forms, H1 and H2, which have inverted orientation. When H1 is in “on” orientation, it expresses whereas H2 is repressed (“off”), and *vice versa*.

⌘ Hin recombinase induces inversion of these genes allowing the expression of different flagellins in some individuals of the bacterial population.

→ These individuals can escape host immune system and proliferate

# **DNA TRANSPOSITION**

**Barbara McClintock (1902-1992) elucidated genetic bases of transposable elements through her studies in maize. She won a Nobel Prize in 1983, 35 years after her first publication on Transposition.**

☞ **Transposable elements (transposons)** are mobile fragments which can move from one site to another site in the genome.

☞ Transposons exist in the genome of all species. Their percentage varies – very high in some species such as human or maize, .., low in *Drosophila* and yeast, ..

☞ Insertion of transposons into new sites can **disrupt gene products** (insertion into coding region) or **change gene expression** (insertion into regulatory sequences)

☞ Transposition is the most common cause of DNA mutations in many organisms.

☞ Transposition is used to disrupt gene functions in Genetic engineering.

**Based on structure and mechanism of action, transposable elements are classified into different groups**

# STRUCTURE AND MECHANISM OF ACTION OF THE THREE FAMILIES OF TRANSPOSABLE ELEMENTS

CLASS DESCRIPTION AND STRUCTURE	GENES IN COMPLETE ELEMENT	MODE OF MOVEMENT	EXAMPLES
<p><b>DNA-only transposons</b></p>  <p>short inverted repeats at each end</p>	encodes transposase	moves as DNA, either excising or following a replicative pathway	P element ( <i>Drosophila</i> ) Ac-Ds (maize) Tn3 and IS1 ( <i>E.coli</i> ) Tam3 (snapdragon)
<p><b>Retroviral-like retrotransposons</b></p>  <p>directly repeated long terminal repeats (LTRs) at ends</p>	encodes reverse transcriptase and resembles retrovirus	moves via an RNA intermediate produced by promoter in LTR	Copia ( <i>Drosophila</i> ) Ty1 (yeast) THE-1 (human) Bs1 (maize)
<p><b>Nonretroviral retrotransposons</b></p>  <p>Poly A at 3' end of RNA transcript; 5' end is often truncated</p>	encodes reverse transcriptase	moves via an RNA intermediate that is often produced from a neighboring promoter	F element ( <i>Drosophila</i> ) L1 (human) Cin4 (maize)
<p>These elements range in length from 1000 to about 12,000 nucleotide pairs; each family contains many members, only a few of which are listed here. In addition to transposable elements, there are selected viruses that can move in and out of host cell chromosomes; these viruses are related to the first two classes of transposons.</p>			

# TRANSPOSITION CAN OCCUR IN TWO WAYS : NON-REPLICATIVE (CUT –AND PASTE) AND REPLICATIVE

## CUT-AND-PASTE (NON-REPLICATIVE) TRANSPOSITION

Excision of the transposon from its initial location on the **donor chromosome** and integration of this transposon into new DNA site on the **target chromosome**

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

- ⌘ Subunits of **transposase**, the enzyme responsible for transposition, bind to the inverted repeats at each end of the transposon and bring them together to form a transpososome
- ⌘ Transposase subunits cleave the junction between the transposon and host DNA
- ⌘ The ends of the excised transposon are joined to cleaved ends of the new site resulting in its insertion in the new site.
- ⌘ DSB at the “old” site is repaired by homologous recombination or NEJ ; gaps at the “new” site are filled by repair polymerases and sealed by DNA ligase → duplication of short repeats of the target DNA

# REPLICATIVE TRANSPOSITION

The replicative transposition follows the following steps :

- ☞ Assembly of transposase subunits on inverted repeats at each end of the transposon and formation of the transpososome
- ☞ Transposase subunits cleave at the end of the transposon to release the 3'OH group at each end. **The transposon is not excised from its initial location. This is the main difference between replicative and non-replicative transposition**
- ☞ The 3'OH ends of the transposon are joined to 5'ends of the “new” cleaved site whereas the 5'P ends of the transposon remain linked to the “old” site
- ☞ Replication generates two copies of the transposon, one remains at the initial location, the other is inserted in a new location

*“Copyright 2002 from Molecular Biology of the Cell  
by Alberts et al. Reproduced by permission of Garland  
Science/Taylor & Francis LLC.”*

# REPLICATIVE TRANSPOSITION PROCESS

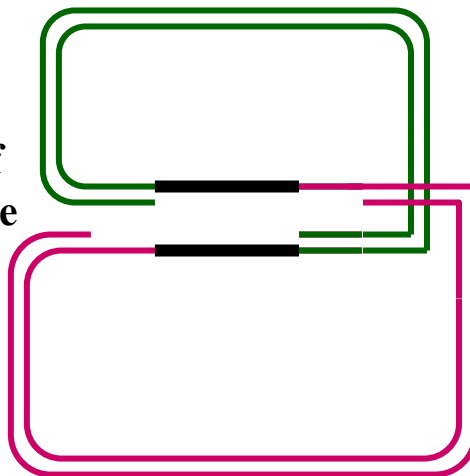

Transposon is cleaved releasing two 3'OH ends

The target DNA is cleaved releasing two 5'P ends

The 3'OH ends of the transposon are ligated to the 5'P ends of target DNA

Replicative transposition results in two copies of the initial transposon

The transposon and adjacent sequences are replicated. The resulting structure is called a cointegrate. Recombination occurs between the two transposon copies

April 2009

*“Adapted from Watson J.D. et al. 2004. Molecular Biology of the Gene. 5<sup>th</sup> edition, p.319, fig 11.22. Benjamin Cummings., CSHL Press”*

34

## TRANSPOSITION OF POLY-A RETROTRANSPOSON

The transposition of a **poly-A retrotransposon** includes many steps :

☞ Transcription of the retrotransposon by cellular RNA polymerase

☞ The resulting mRNA is translated into proteins which bind to its 3'end

☞ The protein-mRNA complex binds to a T-rich site in the target DNA, induces a nick in this site and forms a RNA:DNA hybrid

☞ The 3'end of the cleaved target site is used as a primer to synthesize a cDNA on the RNA template

☞ The initial mRNA is degraded and the second DNA strand is synthesized followed by DNA joining and ligation.

→ A new copy of the poly-A retrotransposon is inserted in a new location

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

# TRANSPOSITION OF RETROVIRAL-LIKE RETROTRANSPOSON

The life cycle of a retrovirus. The integration (↖) of the retrovirus into host genome is catalyzed by a viral enzyme, the integrase

*“Copyright 2002 from Molecular Biology of the Cell by Alberts et al. Reproduced by permission of Garland Science/Taylor & Francis LLC.”*

**Retroviral-like retrotransposon** and retrovirus transpose as follows :

- ☞ Retrotransposon (or prophage) is transcribed from a promoter located within one of the LTR
- ☞ The resulting RNA is then reverse transcribed into a double-stranded cDNA
- ☞ Integrase removes some nucleotides from the 3' end of the double-stranded cDNA
- ☞ The processed retrotransposon is then inserted to a new site on the target DNA

# AN EXAMPLE OF TRANSPOSITION : V(D)J RECOMBINATION

The immune system of vertebrates has to recognize a vast spectrum of “foreign” molecules encountered by the organism during its life time, and to destroy them. The specific recognition of these “foreign” molecules is made by T-cell receptors produced by T cells and antibodies produced by B cells. Take the example of an antibody

An antibody is composed of two light chains and two heavy chains (*figure*). Each chain includes variable and constant regions. Variable regions are involved in the recognition of various antigens.

The diversity of these variable regions is created by differently combining V (variable), D (diveristy) and J (joining) genes in a process called V(D)J recombination (table below)

Element	Immunoglobulin		$\alpha$ : $\beta$ Receptor	
	H	$\kappa + \lambda$	$\beta$	$\alpha$
V segmats	65	70	52	70
D segments	27	—	2	—
J segments	6	5 $\kappa$ 4 $\lambda$	13	61
Number of V region combinations	$3.4 \times 10^6$	$3.4 \times 10^6$	$5.8 \times 10^6$	$5.8 \times 10^6$
Junctional diversity	$3 \times 10^7$	$3 \times 10^7$	$2 \times 10^{11}$	$2 \times 10^{11}$
<b>Total diversity</b>	$10^{14}$	$10^{14}$	$10^{18}$	$10^{18}$

Number of V, D, and J segments contributes to combinatorial diversity. Further changes are introduced by junctional diversity, to give the total number of BCR and TCR

repertoires. DOI: 10.1371/journal.pbio.00000016.t001

Market E., Papavasiliou F.N. 2003. V(D)J recombination and the evolution of the adaptive immune system. *PLoS Biol* 1(1)

# V(D)J RECOMBINATION (continued)

*RSS sequence composed of 7-mer and 9-mer conserved motifs which are bound by recombinases*

Market E., Papavasiliou F.N. 2003. V(D)J recombination and the evolution of the adaptive immune system. *PLoS Biol* 1(1) e16  
 doi:10.1371/journal.pbio.0000016  
 April 2009

V(D)J recombination is a “cut-and-paste” reaction including many steps :

☞ Two recombinases, RAG1 and RAG2, recognize recombination signal sequences (RSS) flanking V, D, J genes and bring them together.

☞ RAG complex makes a single-strand cleavage at the junction between a RSS and V, D, or J gene flanked by this RSS.

☞ In the case of a light chain, the released 3’OH free ends of one of the V genes will then attack the 5’P ends of one of the J gene at random to create a defined VJ combination associated with the C gene

In a heavy chain, the recombination reaction occurs in two steps : (1) random recombination between one D gene and one J gene, (2) subsequent recombination between a V gene and the preformed DJ combination.

V(D)J recombination is similar to Cut-and-Paste recombination, involving recombination sites (RSS) and transposases (RAG1, RAG2) acting in the same way

# SUMMARY

**DNA variations are the consequences of three major phenomena : DNA Mutation, DNA Recombination and Transposition.**

## **DNA MUTATION :**

☞ **Mutations occurred during or just after replication can be repaired by DNA polymerases proofreading activities or Mismatch repair system**

☞ **Other DNA damages, caused by water, chemical or physical agents, can be repaired by one of the four categories of repair systems : (1) Direct reversal, (2) Excision repair systems including Base Excision and Nucleotide excision repair, (3) Recombinational repair systems including Double Strand Break (DSB) and Non Homologous End Joining (NHEJ) repair, (4) Translesion repair.**

## **HOMOLOGOUS RECOMBINATION (HR)**

☞ **HR is the exchange of fragments between two homologous DNA molecules**

☞ **HR induces genetic variability, controls the DSB repair system, regulates gene expression**

☞ **HR can be explained by the Holliday model**

☞ **Recombinational machinery in *E. coli* includes : RecBCD, RecA, RuvAB, RuvC which are responsible of the generation of 3' overhang single strand, strand exchange between homologous DNA, branch migration and resolution of the Holliday junction.**

**Homologs of these recombination proteins are found in eukaryotes.**

April 2009

## **SUMMARY (continued)**

### **SITE-SPECIFIC RECOMBINATION (SSR)**

- ∞ SSR involves the exchange of short sequences called recombination sites**
- ∞ SSR can cause insertion, deletion or inversion of DNA sequences between recombination sites**
- ∞ SSR is used for phage insertion into host genome or to modify gene expression**

### **TRANSPOSITION**

- ∞ Transposable elements are composed of transposon, retroviral-like retrotransposon and poly-A retrotransposon**
- ∞ Transposition can disrupt gene function or change gene expression by insertion into gene coding or regulatory sequences**
- ∞ Transposable elements can operate by non-replicative (cut-and-paste) or replicative process**
- ∞ The retroviral-like and poly-A retrotransposon transpose through an RNA intermediates**

**An example of transposition concerns V(D)J recombination which generates a huge diversity of the immune factors (antibodies and receptors)**
